A 30-year-old woman with no previous medical history presented to the emergency department with a seizure and aggressive behavior. After extensive blood work and imaging studies, she was admitted with HIV inaugural infection (CDC stage C3) and cerebral toxoplasmosis. As the first line of treatment, the patient was started on sulfadiazine and pyrimethamine\textsuperscript{1–3}. After one week, she developed non-oliguric acute kidney injury. Urinary sediment analysis revealed sulfonamide crystals with the morphologic appearance of shocks of wheat (Figures 1 and 2), confirmed by infrared spectroscopy\textsuperscript{4}. Sulfadiazine was replaced with clindamycin, and a notable enhancement was observed after the implementation of vigorous fluid hydration using an alkaline solution (sodium bicarbonate).

\textbf{Figure 1.} Sulfadiazine crystals have an amber color and radial striations (contrast phase microscopy, 400× magnification). Urinary analysis results – density: 1.008; pH: 5; proteins: 15 mg/dL; hemoglobin: 0.75 mg/dL; nitrites/glucose/ketones/bilirubin/urobilinogen: negative.
Acknowledgments

We thank Dr. Vincent Frochot for the infrared spectroscopy analysis.

Conflict of Interest

The authors have no conflict of interest to declare.

Authors’ Contributions

VG writing of the original draft. NMF, SL writing – review and editing.

References

Figure 2. Sulfadiazine crystals are strongly birefringent under polarized light (polarized light, magnification 400×).
